Abstract

Viral infections are a natural and inevitable part of life. In healthy individuals, mortality increases when the body's innate immune system quickly activates, creating a cytokine storm. A rapid and excessive release of cytokines into the bloodstream can cause acute respiratory distress syndrome and death. This communication proposes inhibiting cytokine storm development through forced atopy. Hyper-allergenic skin cream therapy stimulates adaptive immunity to support innate immunity before acute infection.

Keywords: Adaptive immunity; Atopy; Innate immunity; Influenza A; Interleukin- 6; Skin cream

1. Introduction

The human influenza A virus is a natural biological entity that spreads disease annually in the United States. It is the only influenza virus known to cause flu pandemics; its mutations can be highly infectious and spread quickly [1].

Historically, many deaths associated with the “Spanish Flu” pandemic of 1918-1920 may have been due to cytokine storms [2].

Most recently, evidence suggests that the severity of COVID-19 is associated with an increased level of cytokines, and other inflammatory mediators, leading to acute respiratory distress syndrome [3].

Acute respiratory distress syndrome (ARDS) arises when fluid builds up in the tiny air sacs (i.e., alveoli) in your lungs. A study indicates that ARDS is a causative syndrome of death in about 70% of fatal COVID-19 cases [4].

David Martin, Pfizer Senior Medical Director, has stated, “A cytokine storm is generally what leads to otherwise healthy young people dying of the flu” [5]. A cytokine storm leads to the rapid proliferation and activation of T cells, macrophages, and natural killer cells that eventually secrete many inflammatory cytokines, chemokines, and chemical mediators [6].

The innate immune system is the first line of defense against a new pathogen (e.g., mutated virus). It also directs the qualitative and quantitative nature of adaptive immunity. During a SARS-CoV-2 infection, severe symptoms indicate an elevated expression of interleukin-6 (IL-6) [7]. IL-6 is a pleiotropic factor involved in innate and adaptive immunity [8]. Therapies designed to control a cytokine storm include blocking cytokines, corticosteroids, blood purification therapy, and stem cell therapy. Some of these therapies have entered the stage of clinical trials, adverse effects and availability have delayed their widespread application in clinical treatment [9, 10].

Hyper-allergenic skin cream therapy inhibits cytokine storm development by stimulating adaptive immunity and increasing the efficacy of cytokine pleiotropy before acute infection.

2. Discussion

Can hyper-allergenic skin cream therapy (i.e., forced atopy before an infection) support innate immunity to circumvent harmful inflammatory events associated with a cytokine storm? Atopy is a Type 2 immune response to environmental antigens (e.g., allergens) considered harmless. In a study published in the journal *Allergy* (2021) titled, “Atopic status protects from severe complications of COVID-19” the researchers concluded, “Atopic status seems to protect against the most severe, often fatal consequences of SARS-CoV2 infection. Such finding may be of help for future studies investigating how to limit the clinical consequences of this infection” [11].

In a communication published in the journal *European Journal of Gastroenterology & Hepatology* (2020) titled, “Eosinophilic esophagitis: is the Th2 inflammation protective against the severe form of COVID-19?” the researchers write, “Evidence could suggest that eosinophilic esophagitis and other allergic diseases, characterized by a Th2-skewed immunity, may be protective against severe COVID-19 disease and could support the hypothesis that eosinophils have a protective effect on SARS-CoV-2 infection” [12].

In a study published in the journal *Annals of Allergy, Asthma & Immunology* (2020) titled, “Atopy is predictive of a decreased need for hospitalization for coronavirus disease 2019” the researchers write, “The knowledge that atopy is associated with less severe COVID-19 outcomes can be instructive in clinical risk stratification. Further studies are needed to understand the underlying mechanism of these apparent protective physiological factors that may prove advantageous in future prevention and treatment strategies” [13].

Alternatively, does a humoral response defect contribute to cytokine storm fatality? In a study published in the journal *Viruses* (2019) titled, “Cytokine Storm Combined with Humoral Immune Response Defect in Fatal Hemorrhagic Fever with Renal Syndrome Case” the researchers concluded, “We propose that differences in a patient’s humoral immune response to the virus could be a contributing factor in fatal HFRS. Differences in epitope recognition by antibodies from patients with different outcomes of the disease are reported regularly. It has been suggested that changes in epitope recognition could lead to inability of antibodies to interfere with virus replication. In the present HFRS case, changes in the epitope recognition were associated with a low neutralizing antibody titer, which could contribute to pathogenesis and the fatal outcome” [14].

There remains a need for immunomodulatory therapy that dampens the harmful effect of a cytokine storm. Hyper-allergenic skin creams stimulate adaptive immunity to support immune system synergy. Examples of prophylactics that may affect “cytokine storm interference” are described in the United States Patent application number 20210015912 A1 (2019) titled, “Topical hyper-allergenic composition and method of treating using the same” [15].

3. Conclusion

Research efforts continue to explore if atopy before acute infection affects cytokine pleiotropy to inhibit cytokine storm development. In “cytokine storm interference,” hyper-allergenic skin cream therapy is intended to stimulate adaptive immunity in support of innate immunity to reduce the clinical impact of a cytokine storm and minimize sequelae.
